ABSTRACT

In this case report, the authors describe the implementation of a system for collecting patient-reported outcomes and integrating results in an electronic health record. The objective was to identify lessons learned in overcoming barriers to collecting and integrating patient-reported outcomes in an electronic health record. The authors analyzed qualitative data in 42 documents collected from system development meetings, written feedback from users, and clinical observations with practice staff, providers, and patients. Guided by the Unified Theory on the Adoption and Use of Information Technology, 5 emergent themes were identified. Two barriers emerged: (i) uncertain clinical benefit and (ii) time, work flow, and effort constraints. Three facilitators emerged: (iii) process automation, (iv) usable system interfaces, and (v) collecting patient-reported outcomes for the right patient at the right time. For electronic health record-integrated patient-reported outcomes to succeed as useful clinical tools, system designers must ensure the clinical relevance of the information being collected while minimizing provider, staff, and patient burden.

Keywords: patient outcome assessment, work flow, clinical informatics, electronic health record, primary care, patient-reported outcomes

INTRODUCTION

As the US healthcare system increases its focus on accountable and patient-centered care, providers are increasingly asked to collect and use patient-reported outcomes (PROs) in patient care.1–3 For example, the Institute of Medicine recommended that policymakers, as part of Stage 3 Meaningful Use, require providers to collect standardized social and behavioral data in their electronic health records (EHRs).4

Others have proposed incorporating PROs in EHRs to achieve more standardized and efficient clinical documentation and work flow.5–7

Given the importance of social and behavioral factors in health, researchers must understand barriers and facilitators related to integrating PROs in EHRs. Previously, researchers have characterized social, technical, and organizational factors related to EHR adoption and use.8–11

However, despite technological advances that support integrating PROs in EHRs, researchers have rarely empirically examined barriers and facilitators associated with this process.12–15 This research is needed to help design the systems in which PROs are collected and communicated to maximize positive impact on clinical decisions and care quality.3,16 Therefore, the objective of this case report is to describe our experiences and lessons learned in overcoming barriers to implementing an information system that collects PROs in an ambulatory EHR.

CASE DESCRIPTION

Setting

As part of a larger, randomized experiment to evaluate the impact of EHR-integrated PROs on chronic pain care,17 we analyzed 6 family medicine practices affiliated with the University of Florida Health System (UF Health). The practices are staffed by 39 providers, including physicians, physician assistants, and nurse practitioners. A centralized information technology (IT) department manages information systems development and customization for the health system’s practice sites. Clinical and administrative champions from family medicine, pain medicine, and IT collaborated with our team of researchers to develop and implement the system with the aim of improving patient and clinician satisfaction and quality of care for patients with chronic pain.

Information System

We modified and implemented an existing, web-based system that administers computer-adaptive PRO questionnaires, called the Collaborative Health Outcomes Information Registry (CHOIR).18 Next, we developed a messaging interface to send PRO results from CHOIR to the UF Health Epic EHR.

The CHOIR system was developed at Stanford University by a team of informaticists and physicians who provided a no-cost license for our implementation.16,19 CHOIR utilizes a client-server architecture with web-based clinician and patient interfaces that use open source technologies, including jQuery mobile20 and Google Web Toolkit.21 Users can access CHOIR via web browsers on desktop or mobile devices. The primary patient user function is the completion of computer-adaptive PRO assessments using a click- or touch-based input device (Figure 1).22 Clinical user functions include registering patients to complete a PRO assessment, reviewing individual and summary PRO assessment results, longitudinal outcomes tracking, and clinical decision support through the aggregation of PRO result sets.

CHOIR is Health Insurance Portability and Accountability Act (HIPAA) compliant for storing patient information. Moreover, the CHOIR web server interfaces with a computer adaptive testing engine for administering questionnaires and scoring results. Through computer adaptive testing, patient response burden is reduced by ~71%.19 The implementation described in this case was designed to administer 13 PRO questionnaires that were selected by local family and pain physicians as relevant to the assessment and management of chronic pain. The measures include the following from the Patient Reported Outcome Measurement Information System (PROMIS): pain...
interference, pain behavior, fatigue, physical function, sleep disturbance, sleep-related impairment, anger, depression, and anxiety. Each PROMIS measure is assessed via a series of text-based items that are administered computer adaptively for increased efficiency and validity. Each PROMIS measure is resulted on a 0–100 scale, where 10 points represent a one standard deviation change based on a healthy population distribution. In addition, CHOIR computes a population percentage score and attaches a nominal result (e.g., “mild,” “moderate,” or “severe”). In addition to the PROMIS measures, our implementation assesses pain location using a body map and pain intensity (0–10 scale), pain catastrophizing, and risk of opioid-related aberrant behavior.

Beyond choosing PRO assessments for our local implementation, we developed an interface between CHOIR and the UF Health Epic ambulatory EHR. Through this interface, CHOIR loads patient and visit information from the EHR. Then, patients can complete PRO assessments when they arrive for a visit but before they see their provider. After a patient completes the assessment, the server creates a Health Level Seven (HL7) message containing discrete PRO results, a static document summarizing all results (Figure 2), and a patient identifier. CHOIR immediately and securely sends this message to the EHR where results records store the PROs for potential provider review during the visit. Through these results and additional EHR customization, clinicians can view PRO scores in their standard results review interface, graphically trend results over time alongside prescribed medications, and use pre-built templates to insert the PRO results into clinical notes.

**METHODS**

We conducted a qualitative observational study over a 15-month period encompassing the system design and early implementation. The study was approved by the University of Florida Institutional Review Board. Research team members collected notes by hand and computer based on observations and conversations during IT development meetings, clinical practice observations, system demonstrations, and facilitated discussions with providers and staff. Between 1 and 3 research team members scheduled and attended each session. The primary goal in the sessions was to understand user and other stakeholders’
needs and preferences for the system design and implementation. The system demonstrations involved 8 patients and 4 providers. The clinical practice observations and facilitated discussions involved a total of 23 providers: 4 IT developers; 4 health system, or IT administrators; and approximately 15 practice staff members. Some of these stakeholders participated in multiple sessions.

During the design phase, our interactions focused on understanding how to design the technology to be maximally usable and useful in the context of clinical practice. During the implementation phase, our interactions had a similar focus but also involved demonstrations and observations of the technology via screen shots, mock-ups, or actual use. Our notes contained a mix of direct quotes and researcher’s interpretation of the interactions. Also, we obtained verbatim written feedback from practice managers during a facilitated group discussion and from some providers and practice staff via email and/or electronic survey. The electronic survey was administered to assess provider experiences for the larger experimental study, but it also yielded some feedback on the PRO system. In total, the data collection generated 42 documents containing approximately 90 pages of text. Table 1 provides an overview of the data.

Given resource and logistical constraints, we chose only 4 of the 6 practices to initially participate in the randomized experiment. One practice was excluded because it is a residency teaching practice, which created additional logistics challenges to implementation. The second practice was excluded because it is located in an outlying geographic area, which posed challenges for conducting regular data collection. Next, consistent with the larger experimental study design, we used a random number generator to select 2 practices to actually implement the system. Therefore, 6 practices provided data during the design phase, and 2 practices provided data during implementation.

Conceptually, our analysis was guided by the Unified Theory on the Adoption and Use of Information Technology (UTAUT) and its core constructs: performance expectancy, effort expectancy, facilitating conditions, and social influence. These constructs predict adoption and use of IT. Three analysts independently read and scrutinized all data by hand, labeling text and using constant comparison across documents from different data sources (Table 1). Analysts looked for repetition and factors relevant to overcoming barriers to using the PRO system. Next, the analysts met among themselves and identified a single set of themes via consensus. In this process, some preliminary themes from individual analysts were dropped due to a lack of general representation in the data. In other cases, preliminary themes from individual analysts were judged to be similar and thus combined. Next, to increase validity and comprehensiveness of the themes, each analyst independently reviewed the themes while scrutinizing the original data. Last, the analysts met again to discuss and arrive at a single

</table>

Notes: aIn this session, practice managers completed a questionnaire on potential work flow challenges. bFor the larger experimental study, providers completed a monthly survey on experiences with pain care in which they also sometimes commented about assessing or using PROs and related work flows.
with their clinical expertise. However, as the primary facilitating condition to help overcome uncertain clinical benefit, providers and practice staff overwhelmingly described a need to collect PRO data from the right patient at the right time. Along those lines, administrators, practice staff, and providers desired processes to pre-identify specific patient visits for which collecting PRO information would be clearly useful. Moreover, administrators, practice staff, and providers mostly rejected a suggestion that PROs be collected at all visits, despite the potential general relevance to patients’ overall health. Finally, some providers suggested the system have a mechanism to defer discussing problems identified by the PROs to a subsequent visit or specialist referral to ensure their ethical and legal obligations to address PRO results were satisfied.

Barrier 2: Time, work flow, and effort constraints
Time, work flow, and effort constraints represented a barrier that cut across nearly all stakeholders’ feedback on concerns about implementing the system. Essentially all stakeholders expressed that system use must fit within existing work flow slack (e.g., patient wait times) or otherwise reduce clinician, staff, or patient time and effort. This barrier fits with the UTAUT principle that increasing expected effort in using a system lowers intended use. Therefore, clinicians and practice staff strongly supported facilitating conditions, namely process automation and collecting PROs from the right patient at the right time, to enhance system adoption and use. Their desire for automation encompassed multiple tasks, including identification of relevant patients, display of PRO results in the EHR, and administration of the PRO questionnaires. For example, after considering multiple approaches, administration, providers, and staff favored an automated

algorithmic approach to reviewing patients’ history and electronically flagging upcoming visits as appropriate for PRO collection. Also, clinicians preferred automated approaches to displaying the PRO results in the EHR, specifically templates or other shortcuts for inserting PRO results in their clinical notes. Similarly, some providers responded positively to the idea that capturing structured PROs could save time normally spent eliciting similar data during face-to-face patient encounters. Practices varied in their preferences for efficiently administering computerized PRO questionnaires. Some practices preferred PROs be collected in a waiting room while others preferred the exam room. These preferences were based on work flow constraints but also reflected concerns about privacy and security of the devices used to administer the surveys.

As an additional facilitating condition to overcome time, work flow and effort constraints, patients and providers requested highly usable system interfaces for efficiently collecting PRO data and reviewing results. For example, some patients expressed frustration with unfamiliar touchscreen interfaces and insufficient interface feedback when they tried to skip required questions. As discussed above, providers were particularly interested in EHR interfaces that allowed them to easily document PRO results in their notes and interpret PRO summary scores. In response to this feedback, we developed and continue to improve interfaces for easily inserting PRO results into clinical notes, trending results over time, and text-based results that appear alongside numeric PRO scores to indicate their clinical decision making relevance.

DISCUSSION

In this case report, we described the design and implementation of a novel information system for computer-adaptive PRO collection and EHR integration along with related lessons learned. While administrators, practice staff, providers, and patients generally supported this system, our experience produced many lessons learned in terms of how to overcome barriers to system adoption and use. Therefore, this study provides timely and practical insights into system- and practice-level barriers and facilitators to integrating PROs in EHRs. Indeed, our findings align with existing theory on antecedents of IT adoption and use, including effort expectancy, performance expectancy, and facilitating conditions.29,30 Also, our findings coincide with recent research and policy recommendations, including the importance of efficient and feasible data collection and clear clinical usefulness.4,31–33 Furthermore, our findings provide new, management and policy-relevant insights into stakeholders’ perceptions of incorporating PROs in EHRs, such as the desire for process automation and to carefully select which patients report PROs.

This study has limitations. First, the study was limited to one institution and embedded in a larger study on chronic pain. Therefore, future research should explore these findings in more general settings. Second, much of the data collected and the analysis results represent the researcher’s perspectives, which may have introduced bias into the findings. Third, the data collection did not continue long into the system implementation, therefore themes may not represent longer-term stakeholder perspectives. Finally, it is important to point out that the barriers and facilitators identified were not universally reported by each provider, staff member, or patient. Our analysis focused on identifying themes that tended to recur across settings and people, which we judged to provide the most generalizable lessons learned.

In conclusion, for EHR-integrated PROs to succeed as useful clinical tools, system designers must ensure the clinical relevance of the information being collected while minimizing provider, staff, and patient burden. Designers should focus on easy-to-use interfaces, automated PRO collection, and communicating PROs only when directly relevant to a given patient visit. Finally, policymakers and clinical leaders may need to better demonstrate clear clinical usefulness or provide other incentives for practices to routinely incorporate PROs in EHRs.
